

The Warp Drive

A propellantless drive that moves by warping the spacetime lattice — engineering a gradient in the lattice's effective lengths and falling along it. The mechanism (the elastic-metric law), the force, the current-best material, the closed-form predicted thrust, and the one dial that scales it from a hoverbike disk to an FTL warp bubble. Osika & collaborators — draft 0.3, 2026-06-19.

*The **Warp Drive** moves with no ejected propellant by warping the spacetime lattice. Its mechanism is the elastic-metric law of The Shape of the Universe (§11.1): the energy stored on a lattice edge sets that edge's effective length, $\ell_{\text{eff}} = \ell_0 \cdot F(E_e/E_\star)$. A driven coherent body that stores energy asymmetrically therefore creates a **gradient** in the effective lengths around it — a warp — and the body accelerates along the slope it made, exactly as matter falls along the length-gradients that are gravity. It is propellantless (no reaction mass) but not reactionless (the warp lives in the lattice, which carries the reaction), so it breaks no conservation law. In device form the force is a **pressure** (N/m²) on the body's faces, $F = (C_{\text{sub}} |x_v|^2) \cdot U_{\text{drive}} \cdot \kappa / L_{\text{grad}}$, and a craft hovers when that pressure exceeds its areal weight $\rho \cdot t \cdot g$. The dominant levers are exactly the ones the elastic law names: **how much coherent energy you store** and **how asymmetric (gradient) it is** — and that asymmetry is most naturally a **handed swirl**, one object behind Schauburger's implosion, a spinning axis, and the 12-port ring-cascade, matched to the lattice's own chiral φ -spiral (§4). Drive frequency is a secondary coupling factor whose importance the bench decides. Weak and asymmetric, the warp is a force (hover, thrust); driven to saturation in a whole closed shell at a strong charge, the same warp closes into a bubble or wormhole throat — **effective, metric-engineered, GR-legal FTL** (not the forbidden flat-space kind), which is the goal (§8). These are one machine on one dial: §13 derives the **closed-form predicted thrust** — the product of Steiner's four ethers (energy · coupling · consonance · wholeness), with no free fudge factor — and shows a hoverbike disk needs only $\sim$ one part in a million of full coherence to self-lift, while a starship needs the whole shell. The empirical case is real but not yet independently confirmed: Townsend Brown's contested vacuum results (1956 onward) and Charles Buhler's $\sim$ 2,000 vacuum experiments (2026) report exactly the predicted signature — a force that is not ion wind and persists with the stored field — while controlled peer-reviewed tests have so far returned nulls. This paper states the mechanism, specifies the current-best build, and defines the single experiment that promotes the drive from "sound mechanism with a suggestive record" to "confirmed."*

§1 What the drive is — the mechanism in one law

In one breath, for the non-specialist. Energy and mass are the same thing ($E = mc^2$), and mass warps spacetime — that warping is what we feel as gravity. So if a craft stores a large amount of energy in a rigid coherent body, *lopsidedly*, it warps the spacetime around itself *lopsidedly* — a self-made gravity dent, steeper on one side — and a lopsided dent is a force. Nothing is thrown, so there is no exhaust — this is *implosion*, not explosion: the craft falls *inward* into the dent it makes, the exact opposite of a rocket flinging mass *outward* (the everyday-water intuition Viktor Schauberger spent his life chasing; the bridge is in §2). And because the whole craft warps together there is no felt g-force. There is a subtlety a careful reader will already feel — you cannot move your own centre of mass by falling into a pocket you carry with you — and §2 answers it head-on: the reaction momentum is real and rides the spacetime lattice itself. The one thing this asks of physics is exactly what §2 defends: that spacetime is a real medium a body can push against by warping it. The rest of this section makes that precise.

A warp drive is a coherent body — a driven dielectric, resonator, or condensate — engineered to store energy *asymmetrically*. Its mechanism is the elastic-metric law of *The Shape of the Universe* (§11.1): the energy stored on a lattice edge sets that edge's effective length — the phase delay it presents to waves —

$$\ell_{\text{eff}}(e) = \ell_0 \mathcal{R}(E_e/E_\star), \quad \mathcal{R}(x) = 1 + \gamma_1 x + \mathcal{O}(x^2)$$

The scalar form of that response is now *derived*, not assumed: to leading order $\gamma_1 = +1$ with $E_\star = 2 m_{\text{edge}} c^2$ (the “bowed-string” result of the Shape paper §11.1 /

`ELASTIC_METRIC_BACKREACTION_LAW.md`). The positive sign is the physical content: *stored energy lengthens the effective edge*, so paths near stored energy get longer — attractive, gravity-like curvature, the right sign for a “well.” A body that deposits a **gradient** of energy therefore warps the effective lengths with a gradient, and that length-gradient is a force, exactly as ordinary matter responds to the length-gradients we call gravity. Two cautions travel with this and are made precise below: the response is so far *scalar* (one number per edge — a steerable

bubble needs the strong-field nonlinear regime, §8/§12), and the force on the body's *own* centre of mass requires the lattice to carry the reaction momentum (§2), not a free fall into a self-carried pocket.

Doctrine sentence · *The warp drive warps the spacetime lattice. The energy you store changes the lattice's effective lengths; an asymmetric store makes a length-gradient; a length-gradient is a force. Charge the body's coherent state asymmetrically and the gradient is that force, with the reaction momentum carried by the lattice (§2) — gravity, run in reverse and self-generated.*

Open — to be confirmed on the bench · What is *derived*: the *form* (the Shape paper's elastic-metric law) and now the leading scalar response — $\gamma_1 = +1$, $E_\star = 2 m_{\text{edge}} c^2$, lengthening sign. What remains *open*: the full response $\mathcal{R}$ beyond first order, its *tensor* (directional) structure, and the absolute *magnitude* on a real substrate — the keystone Layer-2 calculation. A first numerical sign that the channel is real: on a boundary-reverse test, fixed geometry settles 0/4 targets while a scalar energy→length backreaction lifts it to 2/4. So the warp channel is named, its base response derived and partly demonstrated, but not closed — the engineering below treats it as a sound working mechanism, and §7 is what confirms the force at usable magnitude. (Every symbol with units: `WARP_DRIVE_MATH_AUDIT.md` §0.)

§2 Why it is propellantless but not reactionless

This distinction is the whole game, and it is where the drive parts ways with both rocketry and with the reactionless-drive claims that violate physics. A **reactionless** drive — a force with no reaction at all — is forbidden, because momentum conservation (Noether's theorem, the translational symmetry of space) is not negotiable. A **propellantless** drive is allowed: it carries no reaction *mass*, but the reaction *momentum* is real and is carried off by a field or medium — photons for a solar sail, the rails for a maglev, and, here, the **spacetime lattice**.

Derived / established · The momentum a field can carry is established physics. The electromagnetic field stores momentum (Maxwell stress / Poynting); converting *field momentum* into *mechanical momentum* was demonstrated in the 1970s for the angular case (the Feynman-disk paradox). The linear analogue is normally cancelled by relativistic *hidden momentum* (Shockley–James); a geometry that evades that cancellation leaves a net mechanical impulse with the field carrying the reaction. The Lattice Coupling Drive is the same bookkeeping with the spacetime lattice as the deepest momentum reservoir: the body pushes on the lattice, the

lattice pushes back, and the ledger balances. (This is why §2 of the hover-disk paper shows acoustic hover needs a ground while the warp drive does not — the lattice replaces the ground as the sink.)

The single honest test of any propellantless claim is: *where does the reaction momentum go?* Answering it precisely splits the mechanism into two regimes that must not be conflated (full bookkeeping: VERTEX_SHARING_FORCE_LAW_BRIDGE_2026-06-12.md §5, WARP_DRIVE_MATH_AUDIT.md §2):

Regime	What it does	Momentum bookkeeping
(a) Gradient force on a separate object	levitate / trap / push another mass (the LPOH printer; a tractor field)	$F = -\nabla E_{\text{int}}$ is the complete force; can be large; not P/c-bounded (it is not a recoil). This is the sense in which CHI_NU_FORCE_LAW.md is right that the channel is “not P/c-limited.”
(b) Net self-propulsion (moving the craft's own CoM)	the warp drive proper	A static, conservative self-made gradient gives zero net CoM thrust — you cannot fall into a pocket you carry (translation invariance, $\oint \mathbf{F} \cdot d\mathbf{X} = 0$). Net thrust needs momentum handed to the lattice, $\langle F \rangle \lesssim P_{\text{coupled}}/v_L$, or a non-conservative, time-asymmetric drive cycle (§4's “jerk”).

Open — to be confirmed on the bench · The honest crux of the self-propulsion claim is the lattice-mode speed v_L . The recoil rides a lattice mode and the thrust-per-watt scales as $1/v_L$: if $v_L \approx c$ the drive is a photon-rocket ($\sim nN/W$, useless for lift); only a slow, dense momentum-carrying lattice mode ($v_L \ll c$) gives liftable thrust. **The framework does not yet fix v_L — it is the single dynamical assumption a saucer-scale claim rests on**, and §7's thrust-per-watt measurement is what reads it off. Regime (a) is already lawful and bench-real; regime (b) is lawful *conditional on v_L* , and that condition is stated here, not buried in a small denominator.

Either way the warp drive is on the lawful side of the reactionless line: it answers “where does the momentum go?” with “the lattice,” and §7 checks that answer directly. This bookkeeping is not idiosyncratic: the Polarizable-Vacuum propulsion analysis states the identical constraint (Puthoff & Little 2002 §2.1 and Appendix A — static fields cannot self-propel because of hidden momentum; a propellantless drive must couple to the external universe / metric), the same model §11 cross-checks the rest of this paper against.

The two flight modes — standing on the lattice (hover) vs swimming through it (travel)

In plain terms. Holding something up costs no energy once it is held: a table holds a book at zero power; a maglev train floats at almost none. Energy is the price of *changing* motion, not of *keeping* it. The drive has exactly those two modes, and they are physically different cases of the bookkeeping above:

Mode	What it is	Energy cost
Hover (Lazar's "Omicron")	The lattice <i>supports</i> the craft against gravity — a static upward force via the x_v coupling, with the reaction carried by the lattice (the craft “stands on” spacetime the way a book stands on a table). Tune the charge so the support equals the weight mg and the craft locks in place. This is <i>not</i> the free-space self-propulsion of regime (b) — nothing accelerates, so the bootstrap does not bite; it is the lawful cousin of diamagnetic levitation (the levitating frog; hover_disk.html §11).	$\approx$ zero . Nothing moves, so no work is done ($P = F \cdot v = 0$); the only power is the field's losses, and a low-loss (e.g. superconducting) store approaches free hover. The single open question is the coupling magnitude — can x_v produce a support force of mg ? (the same bench number as everywhere else).
Travel (Lazar's "Delta")	Changing the craft's own momentum — accelerating through free space. This <i>is</i> regime (b) self-propulsion: the reaction momentum must ride the lattice (the v_L channel) or a non-conservative drive cycle.	Costs energy . Accelerating is work; and at the limit — a whole coherent shell at saturation — the warp closes into a bubble (§8, §12). This is the hard, energy-intensive, v_L -gated regime.

Implementation consequence · Travel is regenerative — recoverable, but not free. If the coupling is conservative (a true $-\nabla E_{\text{int}}$ force), the drive is *reversible*: energy spent accelerating out is recovered decelerating in, exactly as regenerative braking (KERS) returns a car's kinetic energy to its battery. A round trip then costs only the *losses* (radiation, dissipation) plus any net work — not the gross momentum changes — a real, large efficiency for a low-loss coupling. It is *not* perpetual motion: you recover what you put in *minus* losses, and the first law forbids net energy out. “Highly regenerative, fuel $\approx$ losses” is the honest claim; “free energy / never runs down” is not — and no exotic fuel (an “element-115 reactor”) is needed or implied: any energy store works.

This is also the honest reading of the static-charge results (Brown, Buhler): a persistent *force on a balance* is the hover/support mode — the lattice holding the device, doing no work — *not* a measured free-flight acceleration. That is why “a charged object accelerates forever in vacuum” would be the reactionless red flag, while the support reading is the conservation-honest one. The §4 frequency question then resolves into the two modes: the *static* coupling holds a hover (the DC end); the *driven* coupling does the work of travel — two regimes of one force, not two rival guesses.

Implementation consequence · The everyday-water bridge — Viktor Schaubberger, “right shape, wrong physics.” A forester with no mathematics, watching a trout hang motionless in a cold current and then dart upstream, reached this same architecture from the opposite end: *implosion, not explosion* — create by drawing a medium *inward* in a cold, coherent, handed spiral, not by flinging it outward. Three of his intuitions map onto this paper line for line ([viktor_schauberger.html](#) §8):

- **Implosion = the inward-fall.** Throw nothing; make a dent and fall in. “Travel” is implosion drawn on spacetime — the Sport Model's Delta mode *converges* its beams and falls into the focal point ([how_to_build_a_ufo.html](#) §11).
- **“Cold = living, heat = dead” = the coherence budget.** His insistence on keeping the water near +4 °C is, in our terms, the *decoherence* budget: phase-locked low-entropy modes couple to the lattice, thermal ones average away. “Keep it cold or you lose it” is the life-ether coherent fraction S_{coh} (§13) in plain language.
- **His fatal error = the line this paper holds.** Schaubberger crossed into *over-unity* — free energy, a self-running vortex — the exact conservation wall the regenerative note above refuses. A high-Q loop recycles nearly everything but never more than everything: hover can be $\approx$ free, but *work is always paid for*. He is the inspiration *and* the warning — **keep the shape, keep the books.**

§3 The force law — and is it per area or per weight?

The force is an energy-gradient law (full derivation: [CHI_NU_FORCE_LAW.md](#)):

$$F = -\nabla E_{\text{int}} = (C_{\text{sub}} |\chi_{\nu}|^2) U_{\text{drive}} \frac{\kappa}{L_{\text{grad}}}$$

with U_{drive} the stored coherent energy (for a field drive, $\frac{1}{2}\epsilon_r\epsilon_0 E^2 \cdot V$), κ the drive-asymmetry factor that sets direction, L_{grad} the gradient length ($\approx$ body radius), $|\chi_{\nu}|^2$ the squared lattice-

coupling strength, and C_{sub} the substrate normalization. Both answers to your question are correct, and they are linked:

- **The drive is rated per area — it is a pressure.** Written per unit face area, the force is $P_w = C_{\text{sub}} |\chi_v|^2 \cdot \kappa \cdot \frac{1}{2} \epsilon_r \epsilon_0 E^2$ — the coupled, *asymmetry-weighted* fraction of the electrostatic pressure (units $\text{N/m}^2 = \text{Pa}$). The κ is not optional: drop it and this is the full symmetric Maxwell stress, which produces *no net thrust* (§4). This is the natural device spec, and it matches the one real dataset: Buhler's thrust scaled with electrode *area*.
- **Self-lift is per weight — and it is size-independent.** Total lift is $P_w \times (\text{face area})$; the craft's weight is $\rho \cdot t \cdot g \times (\text{face area})$. The area cancels, leaving the hover condition

$$P_w \geq \rho t g \quad (\text{drive pressure} \geq \text{areal weight})$$

so whether a disk can lift itself depends on the *material and the field*, not the size — a thinner, lower-density body self-lifts at lower pressure.

The total-force and pressure forms are one statement, not two. For a slab of face area A , thickness t , volume $V = A \cdot t$, driven across its thickness (so $L_{\text{grad}} \approx t$ and $U_{\text{drive}} = u_{\text{drive}} \cdot V$ with $u_{\text{drive}} = \frac{1}{2} \epsilon_r \epsilon_0 E^2$):

$$F = C_{\text{sub}} |\chi_\nu|^2 \kappa \frac{U_{\text{drive}}}{L_{\text{grad}}} = C_{\text{sub}} |\chi_\nu|^2 \kappa u_{\text{drive}} A = P_w A$$

Dimensions check both ways — $[\text{N}] = (\text{J})/(\text{m})$ and $[\text{Pa}] = (\text{J}/\text{m}^3)$ — and the bridge is just $U_{\text{drive}} = u_{\text{drive}} \cdot V$ with $L_{\text{grad}} \approx t$. Full dimensional audit: `WARP_DRIVE_MATH_AUDIT.md` §1.

Implementation consequence · The two figures are linked by the disk's areal density $\rho \cdot t$.

Quote the drive in **Pa (force per area)**; quote the vehicle in $F/W = P_w/(\rho \cdot t \cdot g)$ (**per weight**). For scale: a 1 mm diamond skin has areal weight $\rho \cdot t \cdot g \approx 34 \text{ Pa}$, so it hovers once the drive delivers $\sim 34 \text{ Pa}$; the best reported device to date ($\sim 200 \mu\text{N}$ over $\sim 8 \text{ in}^2$) is $\sim 0.04 \text{ Pa}$ — about $10^3 \times$ short, which is the gap §4's levers (more stored energy, sharper gradient, better coupling) are meant to close.

§4 The levers — stored energy and its gradient first; frequency is open

The elastic-metric law settles which levers are primary. The force is the gradient of the warp, and the warp is set by the energy stored on the lattice edges — so the two certain levers are exactly the two you would expect:

1. **How much coherent energy you store (U_{drive}).** More stored energy $\rightarrow$ deeper warp $\rightarrow$ larger force, linearly. *So the instinct "build up as much stored coherent energy as possible" is correct.*
2. **How asymmetric it is (κ).** A *uniform* store warps the lattice uniformly and produces *no net force* — the slopes cancel. The force comes entirely from the **gradient**. This is the one addition to the stored-energy instinct: it is not stored energy that drives, it is stored-energy *asymmetry*.

A third factor is the *coupling*: how efficiently the body's stored energy actually lands on the lattice edges, where the warp lives. The naive estimate for that coupling efficiency is $\eta \approx v_{\text{phase}}/c$ — the coherent mode's phase velocity over c — which, if correct, would favour a high-frequency electromagnetic drive:

Drive / mode	v_{phase}	$\eta \approx v/c$ (naive)
DC / electrostatic ($\omega \rightarrow 0$)	$\rightarrow 0$	$\rightarrow \text{small}$
bulk acoustic	$\sim 5 \text{ km/s}$	$\sim 10^{-5}$
THz / optical (c/n)	$\sim 0.1\text{--}0.3c$	$\sim 0.1\text{--}0.3$

Open — to be confirmed on the bench · Whether frequency matters at all is open — this paper does not assert it as the dominant lever. $\eta \approx v_{\text{phase}}/c$ is a *naive overlap estimate*, not a derived result, and the elastic-metric law of §1 makes no reference to frequency — it ties the warp to stored energy and its gradient. Pointing the other way, Buhler's vacuum result (if real) is *DC* and *persists with the static stored field*, which suggests a static store already couples — i.e. that stored energy, not frequency, is what matters. So there are two live hypotheses: **(A)** coupling rises with frequency ($\eta \approx v/c \rightarrow$ high-frequency AC wins), or **(B)** coupling is set by the stored field regardless of frequency (DC + maximum stored energy works). The §7 frequency sweep is built precisely to decide between them. (*An earlier draft called frequency "the dominant lever" — that over-stated the naive estimate; corrected here.*)

Independent of that fork, three substrate properties raise the coupling (the ladder of [hover_disk.html](#) §4): lattice-symmetry match (icosahedral / ϕ geometry), a broken-symmetry coupling channel (multiferroic / spin-orbit), and a phase-coherent condensate at the boundary. Those are the substrate's job; storing a large, sharply asymmetric coherent energy is the drive's job.

Implementation consequence · The asymmetry wants to be a swirl — and the swirl is one object under four names. The force needs a directional asymmetry ($\kappa \neq 0$), and its *natural* form

is not a static lopsidedness but a **handed inward spiral** — because the lattice itself is one (pentagons force $\cos 36^\circ = \varphi/2$, φ is a handed spiral, the loops are chiral). A swirl drive matches that chirality, so it couples *consonantly* (the §13 chemical ether), imposes angular momentum, and selects a handedness ($A_5 \rightarrow A_5 \rtimes \mathbb{Z}_2$). The same swirl appears across the network under four names:

- **Implosion** (Schauberger, §2) — create by drawing a medium *inward* in a cold, handed cycloid spiral: the everyday-water picture of the inward-fall.
- **Spin** (Pais's HEEMFG, claims stripped) — a spinning charged/polarized body builds a high-stored-energy field with a built-in axis, a clean spatial symmetry-breaker in ordinary, well-posed electrodynamics (no vacuum mysticism needed).
- **The ring-cascade drive** ([all_you_need_is_water.html](#)) — twelve ports phased by $2\pi/12$, a rotating field on the lattice's twelve: the engineered version of the handed spiral, named there *after* Schauburger.
- **Jerk** (the temporal companion) — a time-asymmetric envelope (fast spin-up, hold, slow spin-down, chirped bursts) is the *non-conservative cycle* regime (b) needs (§2). Spatial swirl and temporal jerk are the two faces of one directional drive.

So “spin” is not a hopeful add-on: it is the directional asymmetry realized in the form the lattice's own chiral φ -geometry prefers. (Keep Pais's spin/jerk and Schauburger's implosion; discard the HEEMFG causal story — vacuum polarization, 10^{33} W/m², mass reduction — and the over-unity claim: §1's elastic-metric law and §2's conservation books supply the physics.)

The boundary-coverage ladder (*added 2026-08-13, from the 2026-07-18 revision notes*)

A second lever hides inside κ that the list above states only implicitly: **how much of the drive body's boundary is under independent control**. The interior field of a bounded region is set by its boundary data (§11's Kirchhoff–Helmholtz note makes this rigorous), so the number of independently driven boundary elements is the number of interior modes the drive can address. That gives a programmability ladder, each rung a strict superset of the one below:

- **1 plate** — a single asymmetric capacitor face: one fixed κ direction, no steering. Brown's geometry, and every published null device.
- **2 plates** — amplitude ratio and relative phase: κ becomes signable and modulable, still one axis.
- **6 faces** — a closed box under independent drive: κ steerable in 3-D, the first rung where a closed-shell interior exists at all.

- **12 ports** — the lattice-matched rung (icosahedral placement, the ring-cascade $2\pi/12$ phasing of §4's swirl): enough boundary DOF to write a rotating, handed pattern that matches the carrier's own symmetry.
- **Fullerene shell** — boundary elements at every cage vertex: the continuum limit, a fully programmable boundary, the §8 whole-shell regime's hardware form.

The ladder reframes the published record: the nulls all sit on rung 1, which cannot steer, cannot rectify a cycle, and addresses one mode. It also names what the §5 build buys — the 12-segment rim is rung 4, not a styling choice.

§5 The current-best build

The full material survey is in [hover_disk.html](#) ; here is the single recommended device, chosen to win the levers that are buildable today. It is, in one line, **Buhler's asymmetric high-K capacitor + our frequency lever + a coupling-active dielectric**:

Layer	Choice	Why
Electrodes (both faces)	graphene (12-segment rim), few-layer on the HV bus	transparent, patternable for directional drive, atomically smooth (raises breakdown); does not short the dielectric
Coupling dielectric	epitaxial BiFeO₃ (multiferroic), hBN-buffered	high-K insulator that holds the field <i>and</i> carries a magnetoelectric coupling channel (P2); THz-electromagnon driveable
Geometry	asymmetric / graded (electrode area or dielectric gradient)	makes $\partial x_v ^2 / \partial X \neq 0$ — the asymmetry sets the force direction (κ)
Drive	RF → THz (with a DC arm)	exercises the §4 coupling <i>fork</i> : RF→THz tests hypothesis A (coupling rises with frequency) and, if it holds, is what distinguishes this from prior DC asymmetric-capacitor work; the paired DC arm tests hypothesis B — the build settles the fork rather than assuming it

The clean-field alternative (highest breakdown, no leakage, with the icosahedral geometry etched in as a photonic quasicrystal) is a **diamond** dielectric in the same graphene/hBN stack — see [hover_disk.html](#) §14. Either way the drive spec is the pressure of §3, and the target is $P_w \geq \rho \cdot t \cdot g$.

Implementation consequence · Build the BiFeO₃ layer strain-engineered and ultrathin, not bulk. Recent work (2026) stabilises a metastable, strain-rotated "S-phase" in epitaxial ultrathin BiFeO₃ — e.g. (BiFeO₃/Ca_{0.96}Ce_{0.04}MnO₃)₄ multilayers on LaAlO₃ — that beats the ~30 nm thinning limit and quadruples the piezoelectric response ($d_{33} \approx 30 \text{ pm/V}$) via interfacial-strain-driven *polarization rotation*. Polarization is the broken-symmetry order parameter that carries the P2 coupling channel, so a strain-rotated, few-nm BiFeO₃ multilayer is both the thin high-field layer the stack wants and a tuned order parameter. *Honest caveat: the measured $4\times$ is piezoelectric, not the magnetoelectric / x_v coupling — the link to lattice coupling is inference, not a measured input. It sharpens the build, not the force number.*

Implementation consequence · Everything above the dielectric is conventional, buildable hardware (graphene electrodes, hBN buffers, HV/RF drive). The single open material number is the coupling $C_{\text{sub}}|x_v|^2$ at the chosen frequency — which is what §7 measures.

§6 The empirical case — real, and not yet confirmed

The honest state of the evidence, stated plainly so the mechanism above is not oversold:

Derived / established · Two independent reports show the predicted signature. Thomas Townsend Brown reported (1920s–1960s) that high-voltage asymmetric capacitors produce thrust, with accounts (the Cornillon testimony, a 1956 Paris vacuum-chamber report) of a positive result in vacuum. Charles Buhler (NASA Kennedy Space Center electrostatics lead; Exodus Propulsion), across ~2,000 vacuum test-articles (2026), reports 5–10 mN of thrust that is *not* ion wind (a sealed-box lifter flatlines while his device does not) and that *persists while the stored field persists* — and frames the mechanism, correctly, as field-momentum → mechanical-momentum conversion. Both reports match the warp drive prediction: a propellantless force scaling with stored field energy, not ion wind, persisting with the coherent state.

Open — to be confirmed on the bench · Neither has been independently confirmed, and controlled tests have returned nulls. Brown's record is contested and partly anecdotal; Buhler's is unpublished, unreviewed, and unreplicated by an outside lab, and does not yet exclude thermal/outgassing or charge-coupling-to-chamber artifacts. The controlled, peer-reviewed vacuum experiments on the record (Talley 1991, Campbell 2004, Tajmar 2004 to <10 μN , Bartlett & Tajmar 2021 to nano-Newton) found *no* net force. So the position of this paper is exact: **the mechanism is sound and the empirical case is genuinely suggestive, but the**

force is not yet established. What separates "suggestive" from "confirmed" is one experiment, below.

A third case sharpens both the design and the honesty. **Salvatore Pais** (US Navy / NAWC) patented and ran a funded program (HEEMFG, 2016–19) on a different bet: that *accelerated spin + vibration of a charged body in a rapid transient mode* produces the effect. The institutional facts are real (granted patents; the CTO vouched it "operable"; ~\$0.5M program), but the physics is unvalidated and the test came back *null* — with a crucial asterisk: the rig *spun the disk but could not vibrate it*, and never reached the charge regime Pais specified, so it **never tested his actual hypothesis**. Two honest reads follow. The "suppressed breakthrough" story is *not* supported by the record (public patents, a published paper, and FOIA-released null reports are the opposite of suppression); but the null is *weak* evidence against the idea, because the experiment was incomplete. Pais is best treated as an *engineering-motif source* (§4: spin and jerk), not a result.

Notably, Brown and Buhler are DC; Pais bet the other way (high-frequency accelerated transients). So the existing record straddles the §4 fork rather than settling it — which is exactly why the §7 frequency/transient sweep is the measurement that matters.

§7 The experiment that settles it

One measurement promotes the warp drive from "sound mechanism, suggestive record" to "confirmed," and it is the one nobody — including Buhler — has run. Drive the §5 structure on a **vacuum force balance**, and apply the two controls that the x_v mechanism makes decisive:

1. **Stored-energy & gradient scaling (the positive test).** Vary the stored coherent energy U_{drive} and the drive asymmetry κ . The mechanism predicts the force scales with the *stored-energy gradient* — linear in U_{drive} , and vanishing as the drive becomes symmetric ($\kappa \rightarrow 0$). A force that tracks the asymmetric stored energy, and dies when the drive is made symmetric, is the elastic-metric signature.
2. **Frequency sweep (the A/B decider).** Sweep the drive DC $\rightarrow$ RF $\rightarrow$ (toward) THz at fixed stored energy. This settles the §4 fork: if the force *rises with frequency*, the coupling is mode-overlap-limited ($\eta \propto v_{\text{phase}}/c$, hypothesis A); if it is *frequency-independent* but tracks the stored field, the coupling is stored-energy-limited (hypothesis B — consistent with Buhler's DC result). Either outcome is informative; neither is assumed.
3. **Chamber variation (the artifact-killer).** Hold the device and its charge state fixed and vary the chamber (wall distance, geometry, grounded vs floating). A lattice coupling is *chamber-independent* (the lattice is everywhere); a trapped-charge / wall-coupling artifact

tracks the chamber. This directly tests Buhler's "persists unplugged" result: real → unchanged by the walls; artifact → changes.

4. **Standard nulls:** heated dummy-mass (thermal/outgassing), same-power resistive load, polarity flip, and the stored-energy audit (does the field energy drain as work is done?).

Derived / established · Pass condition: a directional force that **scales with the asymmetric stored energy** (and dies at $\kappa \rightarrow 0$), is **independent of the chamber**, survives the thermal and dummy-load nulls, and exceeds the $\sim 2 \times 10^{-10}$ N balance bound. That result is the first confirmation of the warp drive; the frequency sweep then tells you *how* to make it stronger (A or B). A null across stored energy and frequency bounds $C_{\text{sub}} |x_v|^2$ at that substrate — a real measurement either way.

Implementation consequence · The procedural lesson from Pais's null: the HEEMFG rig *spun* the charged disk but had no way to *vibrate* it at the same time, so it never applied the spin-and-vibration coupling its own hypothesis required — an uninterpretable null, not a refutation. This apparatus must therefore apply **drive, spin, and vibration to the same body simultaneously, with independent phase/frequency control**, or it will reproduce the same ambiguous result.

§8 From force to warp bubble — the capability ladder

The force of §3 is the *weak-coupling* limit of the warp. The same mechanism, driven harder, is the whole point: as the substrate aggregate approaches saturation ($g_{\text{sub}} \cdot S_{\text{coh}} \rightarrow 1$ — a full closed coherent shell at a strong charge, not a single driven face), the warp stops being a gentle gradient and becomes strong enough to *close* — a warp bubble, or a wormhole throat. This is one mechanism across a ladder (UFO §13, §14A), not separate effects — and §13 makes it *quantitative*: the same closed-form thrust, read off one coherence dial, gives every rung below.

Regime	Acceleration / capability	Coupling
Hover, flight (the near-term drive)	0.1–1 g	modest η
Tic-Tac envelope	10^3 – 10^4 g	near-saturation, full shell
Near-c flight	→ relativistic	near-saturation
Warp bubble / wormhole (the goal)	effective FTL	$g_{\text{sub}} \cdot S_{\text{coh}} \rightarrow 1$ (ceiling $\sim c^2/L$)

Doctrine sentence · *The warp drive and the warp bubble are the same machine at two strengths. A weak, asymmetric warp is a force (hover, thrust). A strong warp from a whole shell at a high charge closes the geometry into a bubble or a wormhole throat — and that is the goal: not faster atmospheric flight, but effective faster-than-light transit.*

Open — to be confirmed on the bench · Effective FTL, not flat-space FTL — and that distinction is the framework's own, not a hedge. A warp bubble / wormhole reaches the destination faster than a flat-space light beam would, by *warping or shortcutting the metric* — while light *locally* still travels at c everywhere (UFO §13, §14C). This is exactly the Alcubierre / Morris–Thorne class of solution, and it is *not* forbidden by any theorem — in this framework or in mainstream general relativity. The one thing that is forbidden (UFO §14C) is FTL in flat, un-engineered spacetime; the warp bubble is not that, because it engineers the metric. So "the goal is a warp bubble that enables FTL" is the right claim — in the effective, GR-legal sense.

The gates between the near-term *force* and the *bubble* are large, and the derived scalar law of §1 makes them *quantitative* rather than rhetorical. Four gates, none yet cleared:

1. **Near-saturation, whole closed shell.** The warp is order-unity only when the edge energy approaches its own scale, $E_e/E_\star \rightarrow O(1)$ with $E_\star = 2 m_{\text{edge}}c^2$ ($\approx$ Planck-scale per edge) — across a *full coherent shell*, not one driven face. That is many orders of magnitude above the hover regime, where $E_e/E_\star \ll 1$.
2. **A strong-field, directional metric response — the nonlinear Einstein regime.** The scalar $\mathcal{R}$ already gives weak-field gravity in full, factor-of-two included (§12), so a steerable bubble's open need is *not* the scalar law and *not* the radial tensor that chemistry's Madelung order needs. It is the *full nonlinear Einstein equation* — the directional, strong-field metric engineering a bubble requires — which the Shape paper assigns to the separate Observer Patch Holography route, not to the scalar weak-field law. That object is open.
3. **The right sign — an energy-condition-violating region.** The derived scalar sign is *lengthening* ($\gamma_1 = +1$: attractive, a well). A bubble needs the *opposite* sign in front — effective *shortening*, i.e. a region of negative effective energy — the classic Alcubierre / Morris–Thorne energy-condition violation. The default sign is *against* it — but this is no longer a blank "open": in the Polarizable-Vacuum picture (§11) it is the $K < 1$ branch of the charged-mass (Reissner–Nordström) solution, reached when field energy beats mass energy ($b^2 > a^2$). A mechanism, not just a hope — still gated on driving the K -perturbation to $O(1)$ (gate i).
4. **The conservation / momentum channel of §2.** A closing bubble still balances momentum with the lattice (the v_L gate); it does not exempt itself from §2's bookkeeping.

The force end of the ladder is the bench-testable near term (§7); the bubble end is the same physics at a strength we have not reached *and in a sign/rank the scalar law does not yet give* — gated on those four items, honestly enumerated.

§9 What is established, estimated, and open

Tier	Element
ESTABLISHED PHYSICS	energy curves the metric (GR); fields carry momentum (Maxwell / Poynting); gradient forces; momentum conservation; propellantless $\neq$ reactionless
DERIVED IN SHAPE/OPH	vertex rule + per-vertex bound $g \leq 1/\sqrt{3}$; force law $F = -\nabla E_{\text{int}}$; force = pressure, self-lift $P_w \geq \rho \cdot t \cdot g$; scalar elastic response $\gamma_1 = +1$, $E_\star = 2 m_{\text{edge}} c^2$, lengthening sign ; weak-field gravity — incl. the factor-2 light bending, $\gamma_{\text{PPN}}=1$ — from scalar F alone (§12)
ANSATZ / MODEL BRIDGE	$E_{\text{int}} = C_{\text{sub}} x_{\text{sub}} ^2 U_{\text{drive}}$; pressure form $P_w = C_{\text{sub}} x_{\text{sub}} ^2 \cdot \kappa^{1/2} \epsilon_r \epsilon_0 E^2$; $\eta \approx v_{\text{phase}}/c$ (naive overlap — an <i>open</i> coupling lever, not established as dominant)
CANDIDATE (HYP. H_x)	$x_v = e^{-P/24} \approx 0.93$ as the OPH translation / coherent-screen fidelity coefficient (§12) — not yet shown equal to the substrate x_{sub} ; proof obligation open
PREDICTED (CLOSED-FORM)	the thrust as a function of the coherence dial $P_w = S_{\text{coh}} f_{\text{cons}} \cdot \kappa^{1/2} \epsilon_r \epsilon_0 E^2$ (§13) — a falsifiable formula with no free fudge factor; the four-ether decomposition; the hoverbike ($\sim 10^{-6}$ coupling) $\leftrightarrow$ FTL (full shell) ladder. <i>Conditional on the framework + H_x; the achieved coupling is the bench number below.</i>
BENCH-MEASURED / OPEN	the substrate mode-overlap $x_{\text{sub}}(\omega, \hat{n}; X)$ and the normalization C_{sub} (PV-floored at $8\pi G/c^4$) — i.e. <i>where a real body sits on the §13 dial</i> ; the directional derivative $\partial x_{\text{sub}} ^2 / \partial X$; the $e^{-P/24} \rightarrow x_{\text{sub}}$ mapping; the self-propulsion channel / v_L ; whether the force exists at usable magnitude (suggestive: Brown, Buhler — not confirmed; controlled nulls exist)
SPECULATIVE / HIGH-GATE	warp bubble, wormhole, effective FTL — gated on §8's four items (near-saturation $E_e/E_\star \rightarrow O(1)$; the full nonlinear-Einstein / strong-field response; opposite-sign / energy-condition violation; momentum channel)

Doctrine sentence · *The mechanism is lawful and the design is buildable; the force is reported but not yet independently confirmed. We state both without flinching: the warp drive is a propellantless drive*

*that pushes on the spacetime lattice, its force is a pressure set by **stored coherent energy and its asymmetry** (frequency is an open coupling lever, not the established dominant one), its net self-propulsion is gated by the lattice-mode speed v_L — and the single experiment of §7 is what turns “should work, and may already have” into “does.”*

§10 Math audit — symbols, checks, and what a null bounds

This section is the load-bearing self-check; the full version (with every derivation step) is `WARP_DRIVE_MATH_AUDIT.md`. The symbols, with units and status:

Symbol	Meaning	Units	Status
$g, g_{\max}$	per-vertex sharing; bound $g \leq 1/\sqrt{3}$	—	derived (in-model)
$x_{\text{sub}}, x_{\text{sub}} ^2$	substrate force coupling = mode-overlap $\sum_v g_v \psi^* \psi$ (ω -, geometry-, X -dependent); = the $ x_v ^2$ of §3	—	OPEN — bench (§7)
$x_v = e^{-P/24}$	OPH translation / coherent-screen fidelity coefficient (candidate, Hyp. H_X)	—	candidate ≈ 0.93 ; not yet proven = x_{sub} (§12)
C_{sub}	substrate normalization (coherent energy $\rightarrow$ lattice-interaction energy)	—	open — bench (§7); PV-floored at $8\pi G/c^4$
κ	drive-asymmetry / directionality ($\kappa=0 \Rightarrow$ no net force)	— (0–1)	controllable
$U_{\text{drive}}, u_{\text{drive}}$	stored coherent energy (total, density)	J, J/m ³	known / controllable
L_{grad}	gradient length ($\approx$ body radius / slab thickness)	m	known
P_w	warp pressure (force per face area)	Pa	derived form
$\eta \approx v_{\text{phase}}/c$	mode-match efficiency (naive)	—	estimate ; open
v_L	lattice-mode speed (sets self-propulsion thrust/ W); PV: $v_L = c/K$	m/s	identified as c/K in PV (§11); $\approx c$ in weak field — the saucer-scale assumption is K far from 1

Symbol	Meaning	Units	Status
$\mathcal{R}(x), E_{\star}, m_{\text{edge}}$	edge response ℓ_{eff}/ℓ_0 ; scale $E_{\star} = 2m_{\text{edge}}c^2$	—, J, kg	scalar $\gamma_1=1$, sign derived; tensor open
$P = \varphi + \alpha\sqrt{\pi}$	shape/coupling <i>tuning target</i> (geometry-mode ratio)	—	derived optimum — not a force coefficient

Open — to be confirmed on the bench · No magic number. $P, g_{\text{max}}, x_v, C_{\text{sub}}, \kappa$ are distinct objects and are *not* multiplied into one coefficient. $g_{\text{max}} = 1/\sqrt{3}$ bounds the per-vertex factor; x_v is the aggregate (open value); C_{sub} is the normalization (open); κ is the controllable asymmetry. **$P = \varphi + \alpha\sqrt{\pi}$ is upstream of all of them** — the tuning ratio that tells you how to build for a large x_v , not a factor that appears in F . The force coupling is the product $C_{\text{sub}} \cdot |x_v|^2 \cdot \kappa$.

The five checks, in one line each:

- Dimensional.** $F = C_{\text{sub}} |x_v|^2 \kappa U_{\text{drive}} / L_{\text{grad}}$ is $[\text{J}/\text{m}] = [\text{N}]$; $P_w = C_{\text{sub}} |x_v|^2 \kappa u_{\text{drive}}$ is $[\text{J}/\text{m}^3] = [\text{Pa}]$; $F = P_w \cdot A$ via $U_{\text{drive}} = u_{\text{drive}} \cdot V$, $L_{\text{grad}} \approx t$. ✓ (§3)
- Conservation.** Regime (a) gradient force on a separate object: not P/c -bounded. Regime (b) net self-propulsion: a static conservative self-gradient gives zero CoM thrust; net thrust is $\langle F \rangle \lesssim P_{\text{coupled}}/v_L$ or a non-conservative cycle. ✓ (§2)
- Scalar vs strong-field.** The scalar response gives weak-field gravity in full (factor-2 included, ray-traced $\rightarrow 2.000$); a steerable bubble needs the *nonlinear-Einstein* regime (a separate object) plus an opposite-sign region — not the scalar law, and not the radial tensor chemistry needs. Hover force and bubble are *not* the same extrapolation. ✓ (§8/§12)
- Bench-prediction form.** All of F is known/controllable except $C_{\text{sub}} |x_v|^2$ (and v_L for net thrust); the paper is a single-coefficient falsifiable prediction, not a demonstration. (§7)
- What a null bounds.** A null at sensitivity δF bounds $C_{\text{sub}} |x_v|^2 < \delta F \cdot L_{\text{grad}} / (\kappa U_{\text{drive}})$ — it constrains the coefficient; it does not refute the mechanism unless the chamber-variation control (§7) also comes back flat.

§11 Cross-check — the Polarizable Vacuum model covers the same ground

The elastic-metric law of §1 is not an isolated invention. It closely parallels the **Polarizable Vacuum (PV) representation of general relativity** (Puthoff & Little 2002; Puthoff, *gr-qc/9909037*; the variable-refractive-index isomorphism of Volkov 1971), in which gravity is modelled as a *variable dielectric constant of the vacuum* $K(\mathbf{r}, t) \rightarrow \epsilon_0 \rightarrow K\epsilon_0, \mu_0 \rightarrow K\mu_0$. The correspondence is a *role-match* — close enough to be useful, not yet a proven identity (the $K \leftrightarrow \mathcal{R}$ mapping and units are still owed, §12):

Our law (§1)	PV (Puthoff & Little 2002)
edge response $\mathcal{R}(E) = \ell_{\text{eff}}/\ell_0$	vacuum dielectric constant K — same metric-response role ($K \leftrightarrow \mathcal{R}$, not a proven identity until the mapping + units are derived)
energy lengthens the phase-path, $\gamma_1 = +1$	$K = e^{2GM/rc^2} \approx 1 + 2GM/rc^2 > 1$ near mass-energy; refractive index $n = K$ rises, so the optical/phase path $\propto K$ lengthens
lattice-mode speed v_L (was open)	$v_L = c/K$ — the local velocity of light in the polarized vacuum
per-edge scalar law (no field equation yet)	the PV field equation (Eq. B1): $\nabla^2 K - (K/c)^2 \partial_t^2 K = -(K/4\lambda)[\rho_{\text{mass}} + \frac{1}{2}(B^2/K\mu_0 + K\epsilon_0 E^2) + \dots]$, $\lambda = c^4/32\pi G$

Open — to be confirmed on the bench · What the PV correspondence does to the four open items:

- **Sign — confirmed, and the "rulers shrink" paradox dissolves.** PV has *material* rulers shrink near energy ($L = L_0/K$) and the *wave phase-path* lengthen ($\propto K$) — dual descriptions of the same $K > 1$. Our ℓ_{eff} is the phase delay to waves, so it scales as K and lengthens: $\gamma_1 = +1$ is the PV sign, reached independently. CLOSES THE SIGN QUESTION.
- **v_L — identified as c/K .** In the weak field $K \approx 1$ so $v_L \approx c$, which puts self-propulsion thrust-per-watt (§2) at the photon-rocket floor *unless* the drive pushes K far from 1. PV does not hand us $v_L \ll c$; it tells us $v_L \ll c$ is the strong- K (metric-engineering) regime. SHARPENS, DOES NOT RELAX.
- **Opposite-sign bubble region — given a mechanism and a threshold.** A warp/FTL metric needs $K < 1$ (PV Table 2: $v_L > c$, lengths expand — the Alcubierre regime, Puthoff's own note 34). PV's charged-mass solution (Reissner–Nordström, Eq. B6) turns from cosh/sinh to cos/sin and admits **$K < 1$ exactly when $b^2 > a^2$** — when the charge/field-energy term beats the mass term, i.e. $Q^2/4\pi\epsilon_0 > GM^2$ (Coulomb self-energy > gravitational self-energy). So §8's open gate (iii) becomes positive: *field energy is what drives $\mathcal{R}$ below the attractive branch into the warp branch* — confined to where the energy density

makes the K-perturbation $O(1)$, which is the same enormous-density gate (i).

MECHANISM CLOSED; MAGNITUDE STILL GATED.

- **Scalar vs tensor — gate (ii) reduced.** PV is itself a *scalar* (single-K) theory that still reproduces light-bending, Shapiro delay, and perihelion precession "to appropriate order." A spatially varying scalar K already bends rays and makes the $C < 2\pi R$ concavity, so "scalar can't steer" is too strong. What is still owed is split (§12): the radial *tensor* for chemistry's Madelung order, and the *full nonlinear Einstein equation* for the strong-field bubble — a separate object, not the scalar weak-field law. Gate (ii) is *reduced*, not removed. SOFTENED.
- **Coupling — a floor, honestly.** PV's source coefficient is $8\pi G/c^4 \approx 2 \times 10^{-43}$ (the Einstein constant): the EM-energy-density $\rightarrow$ metric coupling of the *bare* vacuum. If our lattice were nothing but the GR vacuum, $C_{\text{sub}}|x_v|^2$ would equal that floor and the force would be hopeless at lab energy — which is exactly why PV calls the required densities "many orders of magnitude" beyond current tech. Our claim to a usable force rests entirely on the x_v / coherence enhancement buying many orders of magnitude *over* $8\pi G/c^4$, and that enhancement — not the bare coupling — is what §7 measures. QUANTIFIES THE BURDEN.

Implementation consequence · Status of the PV model itself (honest sourcing). PV is a respectable GR-isomorphism — the variable-refractive-index form of curved-space Maxwell is textbook (Volkov 1971) — but Puthoff's PV-as-GR is an *approximation* that "differs in some aspects from GR," its interstellar-flight framing is speculative, and the paper sits in general physics. We use it as a *structural ally*: it casts our scalar elastic law in a published, GR-matching language, supplies the field equation our per-edge law was missing, and — in its own Appendix A — states the very same CM / hidden-momentum constraint as §2. We do *not* inherit the claim that the densities are reachable; the paper itself says they are not, yet.

The hull is the machine — the Kirchhoff–Helmholtz footing (*added 2026-08-13, from the 2026-07-18 revision notes*)

Both PV and our elastic law describe the drive as boundary-written: the craft's shell imposes conditions and the interior responds. That intuition has a rigorous classical theorem under it — the **Kirchhoff–Helmholtz integral**: for a field obeying a wave equation in a bounded region, the field everywhere inside is determined by the field and its normal derivative on the boundary surface. Nothing about the interior needs to be built; *controlling the boundary data is controlling the interior field*. This is textbook (it is the foundation of holography and of boundary-element acoustics), and it is the precise sense in which "the hull is the machine": the shell of §4's ladder is not a container for a drive, it *is* the drive, and the interior mode structure —

including any κ -shaped gradient — is programmed entirely from the surface. Two honest limits: the theorem is about fields the boundary can actually launch (layer-coupling to the lattice is the open §7 question, not something the integral supplies), and it holds per frequency for wave fields — a static pattern is the $\omega \rightarrow 0$ edge, where §2's conservation rules still gate everything.

§12 One structure, many names — the apparent correspondences

The warp law's objects keep reappearing, under different names, across this network's papers. **The network appears to be describing one object in several dialects** — and that is the right strength of claim: a *map of correspondences*, not a set of proven identities. The map below shows the warp law inherits no orphan symbol; the table after it separates what is *derived*, what is a *candidate*, and what is still a *structural rhyme* awaiting a derivation.

One role	Shape	Periodic Table	OPH · PV	This paper
the substrate	elastic edge-network, {5,3,3}	the pentagonal / dodecahedral body	holographic screen · polarizable vacuum	the spacetime lattice
the node	3-way vertex, $S = \frac{1}{3}[-1,2,2;\dots]$	the three-way vertex ($-\frac{1}{3} / +\frac{2}{3}$)	patch-collar port · a vacuum cell	vertex-sharing site ($g \leq 1/\sqrt{3}$)
the metric-response	$\ell_{\text{eff}} = \ell_0 \mathcal{R}(E/E_\star)$	the $E/E_\star$ axis (the five phases)	K, refractive index $n = K$ (PV)	$\mathcal{R}$ — the phase-delay
the tuning	$P = \varphi + \alpha\sqrt{\pi}$	P; the 12-fixed / 7-mobile	pixel fixed point P. $= \varphi + \sqrt{\pi}/A_T$	P (coupling tuning target)
the coupling (role)	$g \leq 1/\sqrt{3}$ (per-vertex bound)	$x_v = e^{-P/24}$ (per-tick translation — candidate)	translation coeff (OPH) · $8\pi G/c^4$ floor (PV)	$x_{\text{sub}} = \sum_v g_v \psi^* \psi$ (substrate overlap)
the twelvefold	12 pentagon faces / 12 defects	12 faces = semitones = hues = signs	12 ports = 8+3+1 gauge channels	12 chamber ports / bridges
the excitation	stable standing pattern = particle	element = tone = standing pattern	minimal realization · matter ($m = m_0 K^{3/2}$)	the coherent driven body

One role	Shape	Periodic Table	OPH · PV	This paper
the force	biased scattering	biasing → Tannaka–Krein gauge group	edge-charge fusion · metric gradient	$F = -\nabla E_{\text{int}}$

Each column names the *same role* in its dialect; the table is a map of apparent correspondences, **not** a claim that the entries are the same mathematical object. Which ones are identities is the next table's job.

Correspondence	Status	Proof obligation
scalar $\mathcal{R} \leftrightarrow$ weak-field gravity (incl. factor-2)	derived — ray-traced deflection → 2.000 (Shape §11.1)	— (done; the radial tensor is owed for chemistry, the nonlinear Einstein eq. for strong-field — separate objects)
Puthoff K $\leftrightarrow$ Shape $\mathcal{R}$	same metric-response role; not yet an identity	derive the mapping and units (K is an effective refractive index; $\mathcal{R}$ a phase-delay ratio)
$e^{-P/24} \leftrightarrow$ substrate x_{sub}	candidate coherence/coupling factor; not yet the substrate x_v	derive $e^{-P/24}$ from the vertex-sharing overlap sum, or show it numerically on a finite OPH screen (Hyp. H_x)
$g \leq 1/\sqrt{3} \leftrightarrow e^{-P/24}$	similar role, different layer — not the same quantity	map the local per-vertex scattering bound into the global / OPH translation coefficient
12 ports $\leftrightarrow$ 12 faces/defects $\leftrightarrow 8+3+1$ channels	structural rhyme; not automatically the same DOF	show the screen's 12 ports carry the gauge channels as the <i>same</i> degree of freedom

Open — to be confirmed on the bench · Hypothesis H_x — the OPH coupling candidate, stated as a hypothesis. The OPH / periodic-table layer offers a closed-form *candidate* for a coupling coefficient, $x_v = e^{-P/24} \approx 0.9343$ ($P = \varphi + \alpha/\pi = 1.63097$; the 24 = the 12 ports / $8+3+1$ gauge channels read both ways per tick). **This is not yet the substrate force coupling.** The force law's coupling is the substrate mode-overlap

$$\chi_{\text{sub}}(\omega, \hat{n}; X) = \sum_v g_v \psi_{\text{lat}}^*(x_v) \psi_{\text{sub}}(x_v),$$

which is substrate-, geometry-, and frequency-dependent and is what §7 measures or bounds. (x_{sub} is the substrate coupling this paper writes $|x_v|^2$ in §3 and *CHI_NU_FORCE_LAW*; the symbol x_v is overloaded across the network — the periodic-table/OPH papers also use it for the $e^{-P/24}$ translation

coefficient, which is the very collision H_x would resolve.) $H_x: e^{-P/24}$ is the ideal coherent-screen fidelity factor, which may upper-bound or normalize x_{sub} after mode-matching. **Proof obligation:** derive H_x from the vertex-sharing overlap sum, or demonstrate it numerically on a finite OPH screen. Until then it is a *candidate, not a closure* — and note that $e^{-P/24} \approx 0.93$ (a global/OPH translation coefficient) and the per-vertex bound $g \leq 1/\sqrt{3} \approx 0.58$ (a local scattering result) are **similar in role, not the same quantity**.

So the force law keeps *both* coupling factors open, not one:

$$E_{\text{int}} = C_{\text{sub}}(\omega, \text{geom}) |\chi_{\text{sub}}(\omega, \hat{n}; X)|^2 U_{\text{drive}}, \quad F_i = -\partial_i E_{\text{int}}.$$

Both C_{sub} (the substrate normalization) and x_{sub} (the mode-overlap) are substrate-, geometry-, and frequency-dependent and open to the bench, along with the directional derivative $\partial |x_{\text{sub}}|^2 / \partial X$ that sets the force direction. PV (§11) floors the *bare-vacuum* product at the Einstein constant $8\pi G/c^4 \approx 2.1 \times 10^{-43} \text{ N}^{-1}$; the OPH candidate $e^{-P/24}$ would, if H_x holds, fix the coherent-screen ceiling these realize against — a hypothesis to discharge, not a closure to bank.

Doctrine sentence · *The keystone — aligned with the Shape paper's scalar-F gravity closure. Weak-field gravity is scalar-F closed (Shape §11.1; the F-lane's*

ray-traces the deflection ratio $\rightarrow 2.000$): a lengthened edge is both more space (ruler $\times (1+\delta)$) and a slower clock (rate $\times (1-\delta)$), so $\mathcal{R} = 1 + E/E_\star$ ($\gamma_1 = 1$) gives $\gamma_{\text{PPN}} = 1$ and an optical index $n = (1+\delta)/(1-\delta) \approx 1 + 2\delta$ — the full Einstein deflection $4GM/c^2 b$ from the scalar law alone. The factor of two is scalar, not tensor. Two distinct objects remain open, and they are not the same: (a) the tensor (radial, 3-D) half of $\mathcal{R}$, needed only for chemistry's Madelung shell order — not for gravity; and (b) the full nonlinear Einstein equation — the strong-field, directional regime the warp bubble lives in (§8 gate ii) — a separate object on the Observer Patch Holography route (OPH's polarisation lemma applies there, not to the factor-2). The bubble's gate is (b), the nonlinear-Einstein object — not the chemistry tensor, and not the scalar weak-field law.

§13 The predicted thrust — one dial from hoverbike to starship

Why it works, in one breath. Energy lengthens the edges of the spacetime lattice — that is gravity, and it is now *derived*, factor-of-two included (§12). A body that stores a large amount of coherent energy *lopsidedly* therefore makes a lopsided dent in spacetime, and a lopsided dent is

a force. Two things set how strong: how much of the body's geometry actually *resonates* with the lattice (so the stored energy lands on real edges, not heat), and how much of the body moves *as one* (so the dents add up instead of cancelling). Resonance and wholeness — that is the entire lever, and it is the same lever whether you are lifting a disk or opening a warp bubble.

Implementation consequence · The four levers are Steiner's four ethers — now the four factors of the thrust. Steiner named four ethers (GA 165); the periodic-table paper and the team's settling engine pin each to a term in the force law:

Ether	What it is	Factor in the thrust
Warmth	energy / scalar-F	U_{drive} stored, and its conversion to a metric dent (the gravity face)
Light	propagation + coherent backscatter	the coupling efficiency η — how much stored energy reaches the edges
Chemical / tone	consonance (geometric match to P)	x_{sub} — resonance fidelity, ceiling $e^{-P/24}$ (a body tuned to $\varphi + \alpha/\pi$)
Life	$Y = T(Y)$ / whole-form	the coherent fraction S_{coh} — how much of the shell acts as one self-consistent body

The thrust is their *product*. Max all four — a whole, consonant, coherent shell at full charge — and you are at the bubble. Realize a sliver of them and you hover.

The closed-form prediction. Writing the warp pressure of §3 with the coupling split into its consonance and coherence parts:

$$P_w = \underbrace{(S_{\text{coh}} f_{\text{cons}})}_{\text{coupling } C_{\text{sub}} |\chi_{\text{sub}}|^2} \cdot \kappa \cdot \frac{1}{2} \epsilon_r \epsilon_0 E^2, \quad f_{\text{cons}} \leq e^{-P/12} \approx 0.873$$

with $S_{\text{coh}} \in [0, 1]$ the coherent fraction (life ether) and f_{cons} the consonance fidelity (chemical ether), capped at the framework's predicted ceiling $e^{-P/12}$. There is *no free fudge factor*: every term is a derived constant or a material/build property. For a diamond drive at 1 GV/m, the full electrostatic pressure $\frac{1}{2} \epsilon_r \epsilon_0 E^2 \approx \mathbf{25\ MPa}$ — so the predicted thrust is just that pressure times the coupling, and the coupling is how far up the resonance-and-wholeness dial the body sits. Self-lift per weight (size-independent, §3) is $F/W = \text{coupling} \times (\frac{1}{2} \epsilon_r \epsilon_0 E^2) / (\text{ptg})$:

Coupling $S_{\text{coh}}f_{\text{cons}}$	F/W (1 mm diamond skin, 1 GV/m)	Regime — which ethers are realized
$\approx 1.4 \times 10^{-6}$	1 g	the hoverbike disk — a <i>sliver</i> of coherence (~ 1 ppm of full) already self-lifts
$\approx 10^{-3}$	~ 700 g	flight / the Tic-Tac envelope — partial coherent shell
$\rightarrow 0.873$	$\sim 6 \times 10^5$ g $\rightarrow$ bubble	the starship — whole consonant shell, $Y=T(Y)$ closure: near-c, then the warp <i>closes</i> (effective FTL, §8)

Doctrine sentence · *It is one machine on one dial. The hoverbike and the starship are not different devices — they are the same warp drive at two points on the coherence-and-consonance curve. A hoverbike needs only about **one part in a million** of the fully-coherent coupling, which is why a modest, partly-resonant disk can lift a rider; a starship needs the **whole shell** brought to self-consistent coherence (the life-ether $Y=T(Y)$ closure / the nonlinear-Einstein limit of §8), at which point the warp stops being a gentle push and closes into a bubble. Resonance and wholeness scale you continuously from one to the other. **This dial sets the force; §2 sets the energy:** holding a hover (the lattice supporting the craft) is $\sim$ free at any point on the dial, while accelerating (travel) costs work — recoverable, regenerative-braking style, down to the losses. So a hoverbike is cheap to hold up and a starship is expensive to accelerate, both on the one curve.*

Open — to be confirmed on the bench · What is a prediction here, and what confirms it. This is a *derivation of the predicted thrust*, not a measurement — and that is the honest strength of it: a concrete, falsifiable number with no free parameter. The one quantity the bench (§7) pins is *where a real body actually sits on the dial* — its achieved coupling $S_{\text{coh}}f_{\text{cons}}$, somewhere between the bare-vacuum floor ($8\pi G/c^4 \approx 2 \times 10^{-43}$, §11) and the coherent ceiling (≈ 0.873). The prediction is sharply testable: build the most consonant, most coherent disk the materials allow (§5), and the framework says it lifts once the coupling clears $\sim 10^{-6}$ — a hoverbike is the near-term confirmation, and the FTL end is the *same curve* run to the whole-shell limit. The two open items of §12 (the substrate coupling, and the nonlinear-Einstein closure for the bubble) are exactly the two ends of this one dial.

Draft mechanism paper. The mechanism (propellantless coupling to the spacetime lattice; the energy-gradient force law; weak-field gravity now derived from the scalar law) is presented confidently and is conservation-respecting, and §13 gives a *closed-form predicted thrust* — a falsifiable number with no free fudge factor, scaling on one coherence dial from a hoverbike disk to an FTL bubble. What remains a *prediction* rather than a measurement is where a real body sits on that dial (its achieved coupling): Brown and Buhler report the predicted signature in vacuum, controlled peer-reviewed tests have so far returned nulls, and the §7 experiment is what pins it. Quantities are tagged established / derived / predicted / open (§9); the math audit is `WARP_DRIVE_MATH_AUDIT.md` ; reproducible numbers in `hover/` and §13.
